ABSTRACT

OPTIMIZATION OF CO₂ EOR AND STORAGE DESIGN UNDER UNCERTAINTY

Bender, Serdar

Ph.D., Department of Petroleum and Natural Gas Engineering

Supervisor: Prof. Dr. Serhat Akın

December 2016, 119 pages

The combination of CO₂ enhanced oil recovery (EOR) and permanent CO₂ storage in mature oil reservoirs have the potential to provide a critical near-term solution for reducing greenhouse gas emissions. In the literature, although there are many studies about CO₂ storage and EOR, only a few studies have focused on maximizing both the oil recovery and the CO₂ storage. Moreover, these studies are either experimental or conducted using synthetic reservoir models. Typically, pure CO₂ has the property of mixing with oil to swell it, make it lighter, detach it from the rock surfaces, and cause the oil to flow more freely within the reservoir to producer wells. The main aim of this research is to investigate the effects of immiscible CO₂ injection while maximizing CO₂ storage in a mature heavy oil carbonate reservoir located in south east Turkey. Three different nearby natural gas reservoirs with differing amounts of CO₂ (77.17%, 28.15% and 20.65%) and flue gas originating from a cement factory were considered as CO₂ sources. In order to realistically simulate several possible mechanisms such as CO₂ swelling and viscosity reduction a 3D compositional simulation model was built after a detailed fluid characterization study. Effect of injected gas composition, gas oil ratios and injection rates on CO₂ storage and oil recovery were investigated. Impact of these parameters on the project feasibility was studied using an economic model. The highest amount of CO₂ storage (1.63 billion sm³) and cumulative oil production (1.57 MMsm³) was achieved by pure CO₂ injection. As the amount of CO₂ present in the injected gas stream decreased, the oil recovery and the stored CO₂ decreased

as well. It has been observed that optimized GOR values and injection rates contributed to better sweep efficiency, pressure management and higher net present values.

Keywords: CO₂, Storage, EOR, Flue Gas

Olgun petrol sahalarında karbondioksit ile geliştirilmiş petrol kurtarımının ve daimi karbondioksit depolamasının birleştirilmesi, sera gazı emisyonlarının düşürülmesine çözüm olabilir. Literatürde, CO₂ depolanmasına ve geliştirilmiş petrol kurtarımına ait birçok çalışma olmasına rağmen, sadece birkaçı petrol kurtarımının ve CO₂ depolanmasının arttırılmasına odaklanmıştır. Dahası, bu çalışmalar ya deneysel ya da sentetik rezervuar modellerinde yürütülmüştür. Genellikle, saf karbondioksit petrol ile karışma özelliği sayesinde petrolü şişirir, hafif hale getirir, kaya yüzeyinden ayırır ve petrolün rezervuardan üretim kuyularına daha özgürce akmasını sağlar. Bu çalışmanın amacı, Türkiye'nin güney doğusunda bulunan olgun bir ağır petrol karbonat rezervuarında karışmayan CO₂ enjeksiyonunun etkilerini incelemek ve aynı zamanda CO₂ depolanmasını arttırmaktır. CO₂ kaynağı olarak saha yakınında bulunan ve farklı miktarlarda CO₂ içeren (%77.17, %28.15 ve % 20.65) üç farklı doğal gaz kaynağı ve çimento fabrikasından gelen baca gazı kullanılmıştır. CO₂ şişirme ve viskozite düşürme gibi bazı olası mekanizmaları daha gerçekçi simüle etmek amacıyla detaylı akışkan karakterizasyon çalışması sonrasında 3D karışimsal simülasyon modeli oluşturulmuştur. Enjeksiyonu yapılan gaz bileşiminin, gaz petrol oranının ve enjeksiyon debilerinin CO₂ depolanmasına ve petrol kurtarımına etkileri araştırılmıştır. Bu parametrelerin proje fizibilitesine etkileri ekonomik model kullanılarak çalışılmıştır. Saf CO₂ enjeksiyonu ile en yüksek CO₂ depolanması

(1.63 milyar sm³) ve kümülatif petrol üretimi (1.57 milyon sm³) elde edilmiştir. Enjeksiyonu yapılan gazdaki CO₂ miktarı azaldığında, petrol kurtarımı ve depolanan CO₂ miktarı da düşmektedir. Optimize edilmiş gaz petrol oranı değerlerinin ve enjeksiyon debilerinin daha iyi süpürme verimine, daha iyi basınç yönetimine ve daha yüksek net bugünkü değerine katkıda bulunduğu gözlemlenmiştir.

Anahtar Kelimeler: CO₂, Depolama, EOR, Baca Gazı

To My Family

ACKNOWLEDGMENTS

This thesis would not have been possible without the guidance and the help of several individuals who, by any means, contributed and provided their valuable assistance in the preparation and completion of this study.

First of all, I would like to present my truthful gratitude to Prof. Dr. Serhat Akın. Without his valuable guidance, this thesis would not have been completed.

Besides my advisor, I would like to thank the rest of my thesis committee; Prof. Dr. Nurkan Karahanoğlu, Prof. Dr. Abdurrahman Satman, Assoc. Prof. Dr. Ömer İnanç Türeyen, and Asst. Prof. Dr. İsmail Durgut for their encouragement, insightful comments and hard questions.

I would like to acknowledge scholarship support provided by The Scientific and Technological Research Council of Turkey (TUBITAK 2211-D).

I would like to express my gratitude to the TP Production Department since they assisted me obtaining the essential data.

I would like to acknowledge Schlumberger for providing the license of Eclipse and Petrel Software.

CHAPTER 1

INTRODUCTION

Carbon dioxide (CO₂) is the primary anthropogenic greenhouse gas. One of the major CO₂ emitting sources is process industries and cement industry is one of them. Approximately 5% of the anthropogenic CO₂ emissions is released to the atmosphere by the cement industry (Arachchige et al., 2013). Flue gas containing high amount of CO₂ is emitted during cement clinker production and during fuel combustion. Composition of the flue gas depends on the fuel used for combustion process but it mainly consists of nitrogen (N₂), carbon dioxide (CO₂), water vapor (H₂O), oxygen (O₂) and sulfur dioxide (SO₂). Sulfur, nitrogen oxide (NO_x), carbon monoxide (CO), carbon dioxide and dust are some of the air polluting components that may be present in flue gases (Knopse and Walleser, 2004). CO₂ emissions and non-CO₂ emissions produced as flue gas during cement production can be sequestered in underground geologic formations. CO₂ can be sequestered into three geological areas: coal seams, mature or depleted hydrocarbon reservoirs and deep saline aquifers (Bender, 2011). There are four essential mechanisms that hold CO₂ in place: stratigraphic/structural, residual, solubility and mineral trapping (Zhang and Song, 2014). These mechanisms are required for successful geologic CO₂ storage for hundreds to thousands of years. With the lack of required trapping mechanisms, CO₂ will be released into the atmosphere. If there is a good seal, it can be stated that CO₂ will be trapped permanently and will be immobile with the contribution of the residual, solubility and mineral trapping mechanisms. Injecting flue gas into oil reservoirs is very attractive for flue gas sequestration because these reservoirs have structural seals for trapping, these are well studied and characterized fields, these fields have surface facilities and wells, which will also

decrease the capital investments of the storage project. Injecting flue gas into producing oil fields will result in incremental oil recovery and make the storage project more feasible due to reduced costs. In addition, availability of the flue gas source has strong effect on project economics.

The main aim of this research is to investigate the effects of immiscible CO₂ injection while maximizing CO₂ storage in a mature heavy oil carbonate reservoir located in south east Turkey. Three different nearby natural gas reservoirs with differing amounts of CO₂ (77.17%, 28.15% and 20.65%) and flue gas originating from a cement factory were considered as CO₂ sources. In order to realistically simulate several possible mechanisms such as CO₂ swelling and viscosity reduction a 3D compositional simulation model was built after a detailed fluid characterization study. Effect of injected gas composition, gas oil ratios and injection rates on CO₂ storage and oil recovery were investigated. Impact of these parameters on the project feasibility was studied using an economic model.

This thesis consists of seven chapters:

In Chapter 1, information about the scope of this study and each chapter is given. Chapter 2 presents literature review about geological CO₂ storage and information about CO₂ storage sites, CO₂ trapping mechanisms, CO₂ sources and CO₂ capture systems. Chapter 3 gives information about CO₂ properties, CO₂ EOR displacement mechanisms, CO₂ flooding method and screening criteria for CO₂ EOR. In Chapter 4, information about gas sources that can be used for EOR application is given. In Chapter 5, numerical modeling and history matching of the field are discussed. Chapter 6 discusses the optimization of the gas injection and oil recovery. The final chapter concludes the thesis. The work performed and main results are summarized.

CHAPTER 2

GEOLOGICAL CO₂ STORAGE & ENHANCED OIL RECOVERY

In this chapter, CO₂ storage and CO₂ EOR fundamentals are discussed.

2.1 CO₂ Storage

This section provides information about CO₂ storage sites, trapping mechanisms, CO₂ sources and CO₂ capture systems.

2.1.1 CO₂ Storage Sites

CO₂ can be sequestered into three geological structures; these are oil and gas reservoirs, deep saline aquifers and coal seams (Orr, 2004).

2.1.1.1 Oil and Gas Reservoirs

Oil and gas reservoirs are very attractive for CO₂ storage because these reservoirs already have structural seals, which trap oil and gas for millions of years. This demonstrates the safety of these seals for CO₂ sequestration. These reservoirs are also best candidates, because they are well studied and characterized. Most of the fields have seismic analysis, core data and log analysis, well test analysis, PVT analysis, static and dynamic models. These data can be used to design the project, to determine the storage capacity, and to establish project economics and risks. In addition, these fields have surface facilities that will also decrease the capital investments of the storage project. The benefits discussed above about storing CO₂

into oil and gas reservoirs are both for abandoned fields and mature fields. Injecting CO₂ into producing oil fields will result in incremental oil recovery and make the storage project more feasible. There are many reported CO₂ flooding research in the literature. CO₂ can be stored in most of the oil reservoirs however to make the project profitable, there are some screening criteria. Taber (1997) discusses the screening criteria for CO₂ EOR and Jessen et al. (2005) discuss the screening criteria for CO₂ storage.

2.1.1.2 Deep Saline Aquifers

For CO₂ storage, saline aquifers are advantageous in terms of storage capacity and availability. Oil and gas reservoirs or coal seams may not be around the CO₂ emission sources, but saline formations might be due to the fact that saline aquifers are widespread (Pruess et al., 2003). Another advantage is the CO₂ storage capacity of these formations, which is more than other geological storage areas. According to Parson and Keith (1998), storage capacity of deep saline aquifers is between 370-3700 G_t CO₂ while storage capacity of oil and gas reservoirs is between 740-1850 G_t CO₂ and storage capacity of coal beds is between 370-1100 G_t CO₂. However, there are some disadvantages of storing CO₂ in deep saline aquifers. Storing CO₂ in deep saline aquifers has no economic value when compared with EOR projects. According to Bender (2011), geopressured geothermal aquifers might contain dissolved methane and this gas can be produced while sequestering CO₂, which can possibly make the project profitable. Moreover, according to John et al. (1998), mechanical energy (brine rates), thermal energy (hot brine) and chemical energy (dissolved methane) can be obtained from geopressured geothermal aquifers and can be used to decrease the costs of the project. On the other hand, capital investments will be higher for CO₂ storage projects in saline aquifers because there is need to drill wells. Characterization is the other problem for saline aquifers, because aquifers are not thoroughly investigated and increasing the need to do extensive characterizations to decrease the project risk (Stausland, 2014).

2.1.1.3 Coal Seams

Unmineable coal seams are other natural options for geological CO₂ storage, because mining of the coal and combustion will release the sequestered CO₂ into the atmosphere. Coal seams contain methane on pore surfaces of the coal and in fractures as adsorbed gas or free gas. Here, CO₂ is stored by the mechanism of adsorption. Injected CO₂ induces coal matrix and as a result methane is desorbed because coal prefers the adsorption of carbon dioxide over methane (Ripepi, 2009). Injected CO₂ will go through fractures, diffuse into matrix system and then replace methane (Ohga, 2003). The process is called enhanced coal bed methane recovery (ECBM). Sequestering CO₂ into coal seams might be economic by producing methane from these formations (Gale and Freund, 2001).

2.1.2 Trapping Mechanisms

Four basic mechanisms may hold CO₂ in place. These are stratigraphical/structural, residual, solubility and mineral trapping (Zhang and Song, 2014). These mechanisms are required for successful geologic CO₂ storage for hundreds to thousands of years. With the lack of required trapping mechanisms, CO₂ will be released into the atmosphere. If there is a good seal, CO₂ will be trapped permanently and will be immobile with the contribution of the residual, solubility and mineral trapping mechanisms. Figure 1 shows the contribution of the trapping mechanisms to storage security with time (Metz et al., 2005). As can be seen from Figure 1, mineral trapping has the highest storage security, followed by solubility, residual and structural trapping. However, mineral trapping requires long CO₂ residence times (more than 100 years) compared to other trapping mechanisms. Time is a very important parameter while discussing these parameters. These are explained in the following sections.

Figure 1 - Contribution of the trapping mechanisms to storage security with time (Metz et al., 2005)

2.1.2.1 Stratigraphical/Structural Trapping

The first basic mechanism required to store CO₂ as a gas or supercritical fluid is stratigraphical/structural trapping (hydrodynamic trapping) (Law and Bachu, 1996). During CO₂ injection, CO₂ will rise in the reservoir because of buoyancy. In structural trapping CO₂ is trapped under a low permeability cap rock which will prevent the migration of the CO₂ to the surface. There are many combinations of structural traps. Anticline traps, sealing fault traps, salt dome traps and unconformity traps are common examples for structural and stratigraphic traps.

2.1.2.2 Residual Trapping

When CO₂ is injected into reservoir it will flow as a nonwetting phase and invades pores which is a drainage process. As CO₂ continues to move, it will leave these pores and CO₂ saturation in the pores will decrease until gas saturation reaches to residual gas saturation which can be explained by relative permeability hysteresis (Juanes et al., 2006). Imbibition of brine starts when CO₂ leaves these pores and brine disconnects some of the CO₂ in pores where capillary forces are dominant and traps it. Methods like water alternating gas injection are cyclic injection mechanisms, which change the saturation direction and increase the effect of hysteresis (Ghomian, 2008). In this study, only continuous gas injection is discussed.

2.1.2.3 Solubility Trapping

Dissolution of injected CO₂ in formation fluid is called solubility trapping. Solubility of CO₂ will decrease with increase in formation water salinity, temperature and solubility of CO₂ will increase with the increasing pressure (Figure 2). With increasing depth, temperature and salinity will increase and amount of dissolved CO₂ will decrease (Bachu and Adams, 2003). When brine is saturated by CO₂, density of brine will increase and brine will start to move down which will increase the possibility to keep CO₂ underground. However, as can be seen from Figure 1, solubility trapping is a very slow process.

Figure 2 - CO₂ Solubility in water vs pressure and temperature (Dodds et al., 1956)

2.1.2.4 Mineral Trapping

With the dissolution of CO₂ in brine, carbonic acid (H₂CO₃) may form. As a result, pH will decrease and geochemical reactions will start. Carbonic acid will react with other dissolved species and minerals in formation. Dissolved CO₂ will react with divalent cations like Ca²⁺, Mg²⁺ or Fe²⁺ to form carbonate mineral precipitates like calcite, magnesite and siderite (Nghiem et al., 2010). This type of trapping is the most stable one, but long residence times from hundreds to thousands of years (Figure 1) are required. Because of this slow process, contribution of mineral trapping is usually considered as negligible during CO₂ injection (Bachu et al., 2007). Therefore, mineral trapping is neglected in this study.

2.1.3 CO₂ Sources and CO₂ Capture Systems

This section provides information about CO₂ sources and CO₂ capture systems.

2.1.3.1 Sources of CO₂

There are three different sources of CO₂, which can be used for CO₂ EOR and storage purposes: anthropogenic sources, hydrocarbon reservoirs containing CO₂ and natural CO₂ reservoirs. These CO₂ sources might be impure and needs to be processed before injection to increase the efficiency of CO₂ EOR. United States CO₂ EOR projects are good examples where both natural and industrial CO₂ sources are used (Figure 3).

Figure 3 - United States CO₂ EOR project sources (Michael, 2014)

2.1.3.2 CO₂ Capture Systems and Technologies

CO₂ is generally captured from sources that are continuous and able to provide sufficient amount of CO₂. Fuel processing plants, fossil fuel power plants and other industrial plants that produce cement, chemicals, steel and iron etc. are typical candidates (Metz et al., 2005). Pre-combustion capture, oxy-fuel combustion capture, post combustion capture and capture from industrial sources are main CO₂ capture systems from fossil fuel/biomass use (Figure 4). These systems work together with three different separation technologies to separate CO₂ from other gases: separation with sorbents or solvents (chemical and physical absorption), separation with membranes, and cryogenic distillation (Figure 5).

Figure 4 - CO₂ Capture systems (Metz et al., 2005)

Figure 5 - CO₂ Separation systems (CO₂ Capture project, 2008)

2.2 CO₂ EOR

In this section information about CO₂ properties, CO₂ flooding methods and screening criteria for CO₂ EOR is given.

2.2.1 CO₂ Properties

CO₂ is a gas existing in atmosphere, that is composed of a carbon and two oxygen atoms and chemical formula is CO₂. It is important to understand physical properties of CO₂ and chemical reactions of CO₂ to design successful CO₂ EOR and storage projects. Atomic weight of CO₂ is 44.01 g/mol (Metz et al., 2005). CO₂ is in gas form at standard conditions, 1 bar and 0 °C. Liquid CO₂ forms when the pressure is above 5.18 bar and temperature is above -56.5 °C. Solid CO₂ forms at very high pressures when the temperature is above -56.5 °C. Carbon dioxide behaves like a supercritical fluid above critical point that is 31.1 °C and 73.9 bar. Relationship between the three states of CO₂ is presented on CO₂ Phase Diagram in Figure 6.

Figure 6 - CO₂ Phase diagram (Lower, 2016)

During CO₂ injection into reservoirs, CO₂ is injected in liquid form in wellbore because of low temperature and high pressure. However, in the reservoir CO₂ will be in gas or supercritical form because reservoir temperatures are generally higher than 31.1 °C. As a result, there is only gas or supercritical CO₂ should occur. Therefore, it is principal to understand supercriticality of CO₂. Supercritical carbon dioxide will diffuse like gas and it will dissolve in substances like liquid. Supercritical CO₂ is compressible like a gas and will fill and get the shape of a tank. However, it will dissolve in materials like a liquid. Density of supercritical CO₂ is close to density of liquid CO₂ (Figure 7); however, viscosity of CO₂ will always be smaller than the water viscosity but close to gas viscosity (Figure 8). Therefore, CO₂ mobility will be similar to gas mobility at reservoir conditions and it will be buoyant (Oldenburg, 2002). Around critical temperature and pressure, property of gas or supercritical fluid may change sharply with a little change in pressure (Figure 7). In supercritical state, CO₂ has a density like liquid and viscosity like gas.

Figure 7 - CO₂ Density vs temperature and pressure (Bachu, 2003)

Figure 8 - CO₂ Viscosity vs temperature and pressure (Bachu, 2003)

2.2.1 CO₂ EOR Displacement Mechanisms

Two displacement mechanisms may occur during CO₂ injection: miscible and immiscible displacement. Reservoir pressure, temperature and oil composition affect the displacement type. For a specific reservoir, oil composition is constant before CO₂ injection and temperature is constant during CO₂ injection. There is a lowest pressure at which CO₂ and oil are miscible at constant composition and temperature, which is called the minimum miscibility pressure (MMP). Above MMP, displacement mechanism is miscible and below MMP, displacement mechanism is immiscible.

2.2.1.1 Immiscible CO₂ EOR

Immiscible displacement occurs when the reservoir pressure is below MMP. In immiscible displacement, CO₂ and oil will not be miscible and they will not form one phase. Therefore, recovery will be less than a miscible displacement. In immiscible flooding, there are four major mechanisms. First one is oil swelling;

CO₂ dissolves in oil and cause oil swelling. When trapped oil swells, it will come out of the pores. Also, increasing oil saturation with the swelling effect will increase oil relative permeability and so mobility. Second one is viscosity reduction of oil; when CO₂ dissolves in oil, oil viscosity decreases. With the decrease in oil viscosity, its mobility will increase (Mosavat and Torabi, 2014). Also, CO₂ will push the oil with the increasing pressure and oil recovery will increase (Remson, 2010). An empirical correlation proposed by National Petroleum Council was used to calculate the MMP (Ahmed, 2007). According to their study, if the reservoir pressure is below 27° API, minimum MMP is 4000 psi and if the reservoir temperature is between 120 °F and 150 °F, 200 psi needs to be added to the minimum MMP. By using API gravity of 12.4° and reservoir temperature of 122 °F, MMP was found as 4200 psi that is higher than the initial reservoir pressure. Therefore, miscibility fails for our reservoir.

2.2.1.2 Miscible CO₂ EOR

Multiple contact miscible displacement occurs when the pressure is higher than the MMP. Therefore, to design a multiple contact miscible displacement, the MMP needs to be known. Calculation of MMP is well studied (Benham et al., 1959; Michelsen, 1980; Metcalfe et al., 1973; Wang and Orr, 1998; Kuo, 1985; Wang and Orr, 1997; Luks et al., 1987; Noar and Flock, 1986; Johns et al., 1993; Thomas, 2008; Ahmed, 2007). In miscible CO₂ displacement, heavy oil components like C₅-C₃₀ are extracted by CO₂ from oil, some of the CO₂ is dissolved in oil and miscibility occurs after multiple contacts (Taber et al., 1997). To achieve miscibility, medium-light or light oil must be in the reservoir because MMP of heavy oil is very high that cannot be achieved during CO₂ injection. According to Taber et al. (1997), miscibility check fails when API gravity of oil is less than 22 API. Highest oil recovery can be achieved by miscible CO₂ injection.

2.2.3 CO₂ Flooding Methods

In this section, CO₂ flooding methods are discussed; cyclic CO₂ injection, continuous CO₂ injection, water alternating gas injection, tapered water alternating gas injection and carbonated water injection.

2.2.3.1 Cyclic CO₂ Injection (Huff-N-Puff)

Cyclic CO₂ injection technique is a single well CO₂ injection method. In this method, CO₂ is injected from a production well (huff), and then the well is shut in to let the CO₂ soak into the formation (diffuse into the formation). After a while, well is put on production again (Figure 9). After well production decreases to minimum or a preset value, cycle starts again. During soaking period, CO₂ dissolves in oil, swells oil; reduces its viscosity and increases oil saturation and so relative permeability of oil (Wolcott et al., 1995). Slug size, soaking time, injection rate or pressure and number of cycles are design parameters of a cyclic CO₂ injection study. It was observed that oil recovery increases with the increasing slug size and longer soaking times (Bybee, 2007).

Figure 9 - Cyclic CO₂ injection method (Oil, 2016)

2.2.3.2 Continuous CO₂ Injection

In this technique, CO₂ is injected continuously into the reservoir. Injection rate or pressure and slug size are the design parameters for continuous CO₂ injection method. It was shown that oil recovery increases with increasing CO₂ slug size (Hadlow, 1992). Disadvantage of this methodology when compared with other CO₂ flooding techniques is that there is no mobility control in this method. Viscous fingering may occur during CO₂ injection due to low viscosity of CO₂ and adverse mobility ratio (Nasir and Chong, 2009).

2.2.3.3 Water Alternating Gas Injection (WAG)

In this technique, water and CO₂ is injected in cycles. The aim is to increase the efficiency of CO₂ flooding and sweep efficiency by reducing CO₂ channeling. The duty of water is to control the mobility to make the front more stable. The other advantage of using water is that it will flow into high permeable channels so that CO₂ may go into the low perm zones. It can be said that CO₂ tackles microscopic displacement and water deals with macroscopic displacement. Water-gas ratio (WAG ratio), slug size, injection rates or pressures, production rates and cycle timing are the design parameters that have great impact on the success of WAG (Chen et al., 2009).

2.2.3.4 Tapered Water Alternating Gas Injection

This technique is a modification of WAG method. In this technique, WAG ratio is increased or decreased based on the reservoir properties and economics. Project will be like water flooding with a high WAG ratio and project will be like gas flooding with a low WAG ratio. Bender and Yilmaz (2014) showed that in a heavy oil field where CO₂ breakthrough already occurred, increasing WAG ratio will be very effective.

2.2.3.5 Carbonated Water Injection

Carbonated water injection (CWI) or CO₂ enriched water injection is another CO₂ EOR method. In this method, CO₂ and water are injected simultaneously. They might be mixed at the surface or at the downhole. In this method, CO₂ dissolves in water so that mobility of CO₂ is decreased and sweep efficiency is improved (Sohrabi et al., 2009). When compared with continuous CO₂ injection and WAG, CO₂ breakthrough time will increase during CWI due to decreased mobility. CO₂ has higher solubility in oil than water. Therefore, CO₂ will be transferred into oil. CO₂ will swell the oil, reduce the viscosity of oil and increase recovery (Mosavat and Torabi 2014).

2.2.4 Screening Criteria for CO₂ EOR

As discussed before, there are two displacement mechanisms for CO₂ EOR. These are miscible and immiscible displacement. For a miscible displacement, reservoir pressure before injection or during injection needs to be higher than minimum miscibility pressure. However, there are some limitations for achieving MMP. One of these is formation fracture pressure; MMP needs to be lower than the formation fracture pressure to keep the CO₂ in the reservoir. The other one is project economics. Based on these, there are some screening criteria, which need to be reviewed together. Reservoir depth, API gravity, oil viscosity, oil composition, and oil saturation are some of the screening parameters for a successful CO₂ flooding project. Table 1 presents the screening criteria proposed by Taber et al. (1997).

Table 1 - Screening criteria for CO₂ EOR (Taber et al., 1997)

Technical Screening Guides		
	Recommended	Range of Current Projects
Crude Oil		
Gravity, °API	>22	27 to 44
Viscosity, cp	<10	0.3 to 6
Composition	High percentage of intermediate hydrocarbons (especially C ₅ to C ₁₂)	
Reservoir		
Oil saturation, % PV	>20	15 to 70
Type of formation	Sandstone or carbonate and relatively thin unless dipping.	
Average permeability	Not critical if sufficient injection rates can be maintained.	
Depth and temperature	For miscible displacement, depth must be great enough to allow injection pressures greater than the MMP, which increases with temperature (see Fig. 7 of Ref. 1) and for heavier oils. Recommended depths for CO ₂ floods of typical Permian Basin oils follow.	
	Oil Gravity, °API	Depth must be greater than (ft)
For CO ₂ -miscible flooding		
	>40	2,500
	32 to 39.9	2,800
	28 to 31.9	3,300
	22 to 27.9	4,000
	<22	Fails miscible, screen for immiscible*
For immiscible CO ₂ flooding (lower oil recovery)	13 to 21.9	1,800
	<13	All oil reservoirs fail at any depth
At <1,800 ft, all reservoirs fail screening criteria for either miscible or immiscible flooding with supercritical CO ₂		

2.3 Co-Optimization of CO₂ EOR and Storage

As discussed in Section 2.1 and Section 2.2, the aim of CO₂ storage is to maximize the amount of CO₂ sequestered and the aim of the CO₂ EOR is to maximize the oil recovery. The aim of the co-optimization of CO₂ EOR and storage is to maximize the CO₂ storage and oil recovery. Oil recovered and CO₂ sequestered must be maximum when the reservoir is abandoned. CO₂ have been used to increase oil recovery since 1960's. Due to the effect of CO₂ on global warming, not only increasing oil recovery but also increasing the CO₂ storage is an important issue for today's world. In the literature, there are several studies about co-optimization of CO₂ EOR and storage (CCS) (Cakici, 2003; Kavscek, 2002; Kavscek and Cakici, 2004; Kavscek and Wang, 2004; Jahangiri and Zhang, 2012; Leach et al., 2011; Safarzadeh and Motahhari, 2014; Forooghi et al., 2009; Babadagli, 2006; Hitchon, 2013). However, there are only a few applications of co-optimization of CO₂ EOR and storage (CCS) (Hitchon, 2012; Feenstra et al., 2010; Hund and Greenberg, 2010; Bradbury and Wade, 2010; Ashworth et al., 2010). Weyburn oilfield is a good example for a CCS project due to the size of the project and data gathered for a long time. Weyburn CCS project is the first large field application and has been started in 2000 (Hitchon, 2013). A coal-gasification plant located in North Dakota is the source of the injected CO₂ (Mayer et al., 2013). Approximately 20 million tons of anthropogenic CO₂ has been stored in Weyburn (Hitchon, 2013). Optimal conditions for CCS are not same for each field so that more field applications need to be performed. Ghomian (2008), states that density of oil, reservoir capacity for storage, depth of the reservoir, thickness of the reservoir, oil and water in place are important factors that might affect the CCS projects. CCS is still in the development phase and needs development in technology and policy. To maximize the oil recovery and CO₂ storage, there is need to decide the CO₂ injection strategies and to optimize the operating parameters. Kavscek and Cakici (2004) showed that injecting water and CO₂ like a WAG project does not increase the amount of the CO₂ stored. According to their study, shutting in high amount of gas producing oil wells and closing injection wells whose bottom hole pressure become more than

the required pressure, are desired strategies for the co-optimization project. As can be seen from this discussion, well operating parameters impact the results and must be optimized in each case. In this study, producing gas oil ratios and injection rates are changed to optimize CO₂ storage and oil recovery.

2.4 Flue Gas

Flue gases are one of the major contributors to global warming due to their large CO₂ content. Flue gas is a mixture of gases which are produced during combustion of fuel; wood, coal, gas, oil etc. and during the production of the material. It can be produced by a power generator, oven or any other heat required process and released to atmosphere. Composition of a gas depends on the fuel used for combustion process but it mainly consists of nitrogen (N₂), carbon dioxide (CO₂), water vapor (H₂O), oxygen (O₂) and sulfur dioxide (SO₂). Figure 10 shows the global greenhouse emissions by gas (Pachauri and Meyer, 2014). Sulfur, nitrogen oxide (NO_x), carbon monoxide (CO), carbon dioxide and dust are some of the air polluting components that may occur in flue gases. In this study, flue gas produced from a cement factory was used. Cement is a widely used ingredient in construction industry and produced in almost all parts of the world. Cement is used to make concrete. Approximately 5% of the anthropogenic CO₂ emissions are released to the atmosphere by the cement industry (Arachchige, 2013). CO₂ is emitted during cement clinker production and during fuel combustion. For cement production (Figure 11), firstly raw material is prepared. Once the limestone quarry is mined, limestone and other naturally occurring minerals are transported from limestone quarry to the process area. Size of the raw material needs to be reduced and homogenized. As a result, raw material goes into main crusher to make rough ground material and then goes into a second crusher to produce fine ground material. After that, it is moved to grinding mill to produce finer material. After grinding, finer material goes into preheater, which generally works with recycled heat and then goes into kiln system. Material is heated to nearly 1500 °C in kiln system, where most of the energy (90%) is consumed (Lisa and Hanle, 2004). In this part, material gets the required heat to start the clinkering reactions (Nazmul,

2005) and calcinated to decompose the calcium carbonate (CaCO_3) into calcium oxide (CaO) and CO_2 where most of the CO_2 is released (Cement Production, 2010). Then clinker is cooled to increase the cement quality by stopping the reactions and to protect the clinker handling equipment. Last part of the cement production process is finishing grinding mill where gypsum is added and mixed with the clinker during grinding. In the last part gypsum or some other minerals are added to get the required type of cement in terms of strength and setting time (Cement Production, 2010). After these steps, cement is stored, packed and shipped.

Figure 10- Global greenhouse emissions by gas (Pachauri and Meyer, 2014)

Emissions related with cement industry can be divided into two groups: CO₂ emissions and non-CO₂ ones. CO₂ emissions occur during the process of calcination (Eq. 2.1) and occur during the required energy production. During calcination, approximately 50% of the CO₂ is released. 40% of the CO₂ is released during fossil fuel combustion. 5% of the CO₂ is released during transportation and another 5% is released during electricity consumption (Mahasenan et al., 2005). According to Portland Cement Association (PCA), average CO₂ released during the production of Portland cement in USA is 0.927 kg of CO₂ per 1 kg of cement (Marceau et al., 2006). Whereas gross CO₂ emissions factor for China's cement is 0.883 kg of CO₂ per 1 kg of cement, 0.415 kg comes from calcining process and 0.467 kg comes from energy production (Shen et al., 2014). SO_x, NO_x, CO, N₂, O₂ and volatile organic compounds and dust might be released during cement production. Among these CO₂, NO_x, SO_x, CO and some of the volatile organic compounds are greenhouse gases. Amount of these emissions is based on cement type, cement production method and type of fuels used for the process. In this study, amount of CO₂ emissions is calculated by using clinker production data of the factory. Detailed information about the cement factory is given in Chapter 4.4 and flue gas stream composition and properties used for simulation are given in Table 9.

Injection of flue gas containing mostly N₂ and CO₂ might increase oil recovery with energy provided by both and with the swelling and viscosity reduction effect of CO₂. In addition to these, if the project becomes miscible with increasing pressure, oil recovery will be higher. However, high percentage of N₂ in the flue gas will increase the MMP of the flue gas so that oil recovery will be less than miscible CO₂ injection. According to Huang (1997), CO₂ works better than flue gas for heavy oils at high pressures. Shokoya et al. (2005) states that with increase in CO₂ amount in flue gas may increase the oil recovery for the light oil. CO₂ EOR might have better oil recovery but capturing CO₂ from flue gas will increase the project costs. CO₂ capture from flue gas will cost \$25-70 per tons of CO₂ but large quantities of flue gas are available for a lower cost (Dong and Huang, 2002).

CHAPTER 3

STATEMENT OF PROBLEM

There are many studies about CO₂ storage and EOR; however, only a few studies have been made on flue gas injection (Koch and Hutchinson, 1958; Fong et al., 1992; Huang, 1997; Zhang et al., 2006; Shokoya et al., 2005; Ossa et al., 2010). Majority of these studies focused on maximizing the oil recovery and did not deal with the CO₂ storage. In addition, these studies are experimental or conducted using synthetic reservoir models. The main aim of this research is to investigate the effects of immiscible CO₂ injection while maximizing CO₂ storage in a mature heavy oil carbonate reservoir located in south east Turkey. Three different nearby natural gas reservoirs with differing amounts of CO₂ (77.17%, 28.15% and 20.65%) and flue gas originating from a cement factory were considered as CO₂ sources. CO₂ can be sequestered by injecting raw flue gas that will decrease the CAPEX and OPEX of the project because there is no need to invest on capturing equipment. Transportation of CO₂ is another major expense. However, cement factory discussed in this study is close to oil field and there is a pipeline for transportation, which was built previously for another project. To make the flue gas injection project comparable, pure CO₂ injection, natural gas injection, and high CO₂ percentage natural gas injection from nearby natural gas reservoirs have been studied. Comparisons were made after conducting a detailed field-wide compositional simulation study. CO₂ storage was conducted by injecting flue gas and CO₂. Effects of the injected gas composition and various operating strategies such as producing gas oil ratio and CO₂ injection rate have been studied. These parameters were optimized by changing their values and effects on oil recovery and CO₂ storage were discussed. In addition to these, economic analysis was performed for each scenario.

CHAPTER 4

SOURCES AVAILABLE FOR STORAGE & EOR APPLICATION AND PVT TESTS

There are three different sources of CO₂ which can be used for CO₂ EOR and storage purposes. These are anthropogenic sources, hydrocarbon reservoirs containing CO₂ and natural CO₂ reservoirs. There are three natural CO₂ reservoirs around the oil field. All of them consist mostly of methane and CO₂ gases. These are named as gas source A, gas source B, and gas source C (Figure 12). Also, there is one industrial area close to the mature oil field. Industrial areas are one of the major contributors of carbon dioxide emissions. Flue gas produced from a cement factory located in this area, will be injected in the mature oil field. Tests given in this chapter were conducted by Turkish Petroleum Research Center.

Figure 12 - Distance of the sources to the main camp

4.1 Gas Source A

Gas source A is a natural CO₂ reservoir. Reservoir lithology is dolomitic limestone. Field was discovered in 1977. Reservoir depth is 2250 m and water gas contact is -1730 m. Initial reservoir pressure is 3040 psi and reservoir temperature is 160 °F. Original gas in place is approximately 1.3 billion sm³ with a recovery factor of 70 %. Field was developed with 7 wells and 200 million sm³ of gas was produced between 2003 and 2012. Produced gas was used to apply CO₂ EOR. In 2012, it was decided to suspend the CO₂ EOR project due to lack of surface facilities. Source A consists of mostly CO₂. Mole percentage of CO₂ is 77 %. Table 2 represents the gas composition of source A. Table 3 shows source A reservoir gas properties. Table 4 presents source A reservoir gas PVT properties.

4.2 Gas Source B

Gas source B is a natural gas reservoir with abundant CO₂. Reservoir lithology is dolomitic limestone. Field was discovered in 2010. Reservoir depth is 3500 m. Initial reservoir pressure is 3944 psi and reservoir temperature is 218 °F. Original gas in place of gas source B is approximately 200 million sm³ with a recovery factor of 70 %. Field is currently under development. 1 million sm³ of gas was produced

in 2010. Production was ended in 2010 due to decreased gas prices and lack of market. Gas source B consists mostly methane. Mole percentage of methane is 60 % and mole percentage of CO₂ is 28 %. Table 5 represents the gas composition of gas source B. Table 6 shows gas source B gas properties.

4.3 Gas Source C

Gas source C is a natural gas reservoir with abundant CO₂. Reservoir lithology is dolomitic limestone. Field was discovered in 2015. Reservoir depth is 2500 m. Initial reservoir pressure is 3361 psi and reservoir temperature is 180 °F. Original gas in place of gas source C is approximately 70 million sm³ with a recovery factor of 50 %. Field is currently under development. Current reserve is approximately 35 million sm³. Gas source C consists of mostly methane. Mole percentage of methane is 63.11 % and mole percentage of CO₂ is 20.65 %. Table 7 represents the gas composition of gas source C. Table 8 shows gas source C gas properties.

4.4 Cement Factory

Cement factory located approximately 100 km to the base camp started production in 1975. Company's facilities were reconstituted in 1980 to be used with natural gas and coal as an alternative fuel to oil after oil crisis of 1973 and 1979 (About Mardin Cement, 2016) . Cement factory's natural gas requirement had been supplied between 1982 and 2012 from a natural gas field connected to main camp. To transport the natural gas from the main camp to factory, 100 km long pipeline was constructed. In this study, the idea is to use the same pipeline for flue gas transportation to reduce the project costs. Instead of transporting natural gas from the camp to factory, flue gas will be transported from factory to main camp and then to the mature oil field compressor station. Pipeline between the main camp and the oil field compressor station is 10 km long. Note that cement factory is producing 2,400 tons of clinker per day. To calculate the CO_2 emitted during cement production, clinker emission factor needs to be determined. Clinker emission factor was calculated by using (Eq. 4.1) and fraction of lime in clinker is taken as 64.6 percent, which is IPCC default value (Gibbs et al., 2001). Therefore, clinker emission factor is calculated as 0.507 tons of CO_2 per tons of clinker (Gibbs et al., 2001). By using this clinker emission factor, CO_2 emission is calculated as 1,217 tons/day from calcining process and CO_2 emission from fuel combustion is calculated as 973.6 tons/day. Total possible gas flow rates are given in Table 9 for

different operating levels of cement factory. Flue gas composition used in this study given in Table 9 is taken from literature. It is assumed that NO_x, SO₂, O₂ and H₂O are removed before injecting into reservoir.

$$EF_{\text{clinker}} = \text{fraction CaO} \times (44.01 \text{ g/mole CO}_2 / 56.08 \text{ g/mole CaO}) \quad (4.1)$$

Table 9 - Flue gas stream gas composition and properties used for simulation (Nazmul, 2005)

Total Gas Mass Flow , kg/hr	171,312	256,968	342,624

4.5 Mature Oil Field PVT Tests

PVT properties of reservoir fluid and injected gases are necessary for simulation. To know the fluid behavior in the reservoir, in wellbore, at the surface and at the separator, fluid properties at different temperatures and pressures must be estimated. Also for EOR operations like CO₂ flooding requires detailed information about PVT tests applied with the mature oil fields oil and gas source. Table 10 represents the summary of PVT measurements.

Table 10 - PVT Report summary (Demir, 2016)

PVT Report Summary			
	Oil	Oil + Gas Source A Gas

Oil Viscosity	387.5	63.4	cp

4.5.1 Constant Composition Expansion

Constant composition expansion test, which is also known as flash vaporization test, was conducted in Turkish Petroleum Research Laboratories. Tests were conducted at reservoir temperature of 132 °F. First oil was put in a cell whose pressure is above initial reservoir pressure. Following this, pressure was gradually reduced at constant temperature. With the decrease in pressure, oil expanded and expanding volume was recorded. Measurements were done after phase equilibrium had been reached each time. Gas evolved below bubble point pressure from oil was not separated during measurements. Therefore, composition of the cell is known and constant during experiment. Bubble point pressure, bubble point density, thermal expansion of oil, isothermal compressibility of oil at pressures above bubble point and relative volume was measured. As mentioned, to prepare the cell,

it was heated to 132 °F and thermal expansion of oil was calculated from the volume expansion of the cell (Table 10). Table 11 shows one phase oil isothermal compressibility for oil. Table 12 presents relative volumes for oil, oil and gas mixture. Oil formation volume factors for different pressures above bubble point pressure were calculated by dividing total volume of the cell divided by volume of stock tank oil. Calculated Bo values above bubble point pressure are given in Table 13.

Table 11 - One phase oil isothermal compressibility (Demir, 2016)

One Phase Oil Isothermal Compressibility $1/\text{psig} \times 10^{-6}$	
Pressure, psig	Oil
2000	4.4085

4.5.2 Differential Liberation Expansion (DLE)

Differential liberation test which is also known as differential vaporization test is applied to mimic the reservoir depletion process. Aim of this test is to generate PVT data below bubble point pressure. Test was conducted with oil and gas mixture. Tests were conducted at reservoir temperature of 132 °F. Oil was put in a cell where pressure was above bubble point pressure and pressure was gradually reduced at constant temperature. Measurements were conducted after phase equilibrium had been reached each time. Below bubble point pressure, gas evolved from oil was

separated after phase equilibrium had been reached at each pressure. Oil and gas volumes, densities, specific gravities, gas expansion and gas compressibility were measured at each pressure. Separated gas composition was measured by using a gas chromatograph. Measurements continued until atmospheric pressure is reached and at the end, temperature is decreased to 60 °F for last measurement only. Solution gas oil ratio, gas oil ratio and oil formation volume factors are then calculated.

Oil formation volume factor, oil and gas densities, GOR measured by differential liberation expansion test below bubble point pressure and oil formation volume factor, oil and gas densities measured by constant composition expansion test above bubble point pressure are given in Table 13. Table 14 shows oil gravity and density at standard conditions. Gas composition is given in Table 2. Table 3 shows gas properties and Table 4 presents specific gravity, Z , B_g and gas viscosity of gas. Figure 13 shows crude oil formation factor and viscosity - pressure relationship for heavy oil sample. Oil viscosity decreases until bubble point pressure (50 psig) and then increases due to release of the dissolved gas. Bubble point pressure increases until bubble point pressure (50 psig) due to swelling of oil and starts to decrease above bubble point pressure. Figure 14 shows oil formation factor, solution gas oil ratio and viscosity - pressure relationship when crude oil is combined with source gas A. As can be seen, oil viscosity at 2000 psig can be reduced from 559 cp to 63.37 cp by injecting source A gas. (Figure 13).

4.5.3 Viscosity Measurement

Oil viscosity measurements were carried out by using a rolling-ball viscometer. Test was initiated at a pressure of 3000 psig and temperature of 132 °F. Then, pressure was decreased gradually. Measurements were conducted after phase equilibrium reached. Viscosities were measured for each pressure step above and below bubble point pressures. Evolved gas was separated below bubble point pressures and then oil and gas viscosities were measured. Viscosity measurements for oil and gas mixture are given in Table 15.

CHAPTER 5

NUMERICAL MODELING AND HISTORY MATCHING

In this section, detailed information about the field production history, injection history, geologic description, rock and fluid properties, fluid characterization study, lumping scheme, equation of state tuning, model construction and history matching are given. Aim of this section is to build a dynamic model calibrated with historical production and pressure data to realistically simulate CO₂ injection. Eclipse 300 and Petrel software were used for simulations. Measured parameters such as porosity, permeability, relative permeability, capillary pressure data, and fluid PVT parameters were used in the reservoir model.

5.1 Field Data

Heavy oil carbonate reservoir located in South East Turkey was discovered in 1985 (Bender and Yilmaz, 2014). The reservoir commenced primary production in 1985 and it was developed with 41 wells (Figure 15). In this figure, green dots represent the production wells, blue dots represent the injection wells, and the area between the two red lines shows the production area. Moreover, the blue dashed lines show the faults, and the pink dashed curves show the surface elevation contours. Peak daily oil production reached to 300 sm³/day in 1987 (Figure 16). There was a sharp decline after 1987 due to lack of pressure support, low API and high oil viscosity. Production plateau period had started in 1994 and continued until 2002. In order to remediate production, continuous CO₂ injection was started in May 2003 by using 7 injection wells. The effect of the CO₂ injection on oil production was seen after 12 months of injection, also corresponding to breakthrough time of CO₂. It was observed that oil production increased as a result of CO₂ injection in the field.

Due to high producing gas oil ratios in the production wells and low sweep efficiencies, continuous CO₂ injection was converted to water alternating gas injection in 2007. More than 240 Msm³ of additional oil was produced by CO₂ injection. 900 sm³ of CO₂ was injected to produce 1 sm³ of oil. CO₂ flooding showed a great success in this heavy oil field. CO₂ kept up the required energy support for the production. CO₂ decreased the oil viscosity by swelling that also lead to increase in oil saturation so that oil relative permeability was increased. However, after stopping WAG injection in 2012 due to depletion of CO₂ reservoir, decline in oil production has started again. Details of the CO₂ reservoir are given in Section 4.1.

Figure 15- Field structure map (Bender and Yilmaz, 2014)

Figure 16 - Field production and injection history

5.2 Geologic Description

The heavy oil field is located in a tectonically active area dominated by WSW-ENE oriented faults, anticlinal features and southerly formation dips (Bender and Yilmaz, 2014). Southwest to northeast oriented sealing normal fault together with three orthogonal faults defines the northern and western boundaries of the reservoir. Crest of the anticline leans to this sealing fault and dips to the south. In addition to this fault there are three partially sealing northwest to southeast oriented strike slip partially sealing faults. Main production formation has an average thickness of 60 m. There are three facies at three different depths in the reservoir identified by core data, drill stem test results, Density-Neutron logs, and Gamma Ray logs. Figure 17 shows the petrographic and log characteristics of these facies. Bottom layer is 10% to 18% of porosity bearing wackestone with very low permeability. In contrast, the second layer has higher porosity (15% to 25%) and low permeability (Cobanoglu, 2001). Topmost facies is porosity (22% to 30%) bearing grainstone with the highest permeability where main production is taking place. Figure 18 presents a simple conceptual model of the reservoir where a cap rock lies above the production layers. Below this cap rock, aforementioned facies of the producing formation are

present. Below these layers there is a weak aquifer. Due to the low permeability of the bottom most facies, there is little energy support from this aquifer. Additional information about the geologic description of the field is reported elsewhere (Demiral et al., 1995).

Figure 17 - Petrographic and log characteristics of the reservoir (Bender and Yilmaz, 2014)

Figure 18 – Conceptual model of the reservoir

5.3 Rock and Fluid Properties

By using well logs and core data porosity distribution was obtained (Figure 19). The porosity distribution shows that porosity decreases as the depth increases. Porosity and permeability values determined from the core data and permeability values determined from drill stem tests were used to establish a relationship between porosity and permeability for each layer (Figure 20). Equations 5.1, 5.2, 5.3 and 5.4 represent the relationship for each of the aforementioned facies. As can be seen from Figure 17 and Figure 20, there is a large difference in permeability and porosity values of the topmost layer to those of other layers. In Figure 20, blue dots represent porosity and permeability values obtained from core analysis whereas red dots show permeability values calculated from drill stem tests. It can be seen that drill stem test permeability is higher than the core permeability because there are vugs and fissures in this field and it is hard to see these in core analysis. Therefore, slope of the line of the core data was used and that line was shifted to drill stem test data and then a relationship found between porosity and permeability values. Available special core analysis tests were used to construct relative permeability curves representing oil-water and gas-oil system (Figure 21). Leverett J-function was used to combine all capillary pressure measurements obtained from cores (Figure 22). Initial water saturation for each grid cell was calculated by using the constructed J-function. Similar plots were developed for layers 2 and 3.

$$Permeability = 0.0006 \times e^{41.595 \times Porosity} \quad (5.1)$$

$$Permeability = 1 \times 10^{-7} \times e^{85.438 \times Porosity} \quad (5.2)$$

$$Permeability = 4 \times 10^{-5} \times e^{51.05 \times Porosity} \quad (5.3)$$

$$Permeability = 0.0047 \times e^{21.175 \times Porosity} \quad (5.4)$$

5.4 Fluid Characterization for Compositional Simulation

The main aim of this research is to investigate the effects of immiscible CO₂ injection while maximizing CO₂ storage in a mature heavy oil carbonate reservoir located in south east Turkey. Three different nearby natural gas reservoirs with differing amounts of CO₂ (77.17%, 28.15% and 20.65%) and flue gas originating from a cement factory were considered as CO₂ sources. In order to realistically simulate several possible mechanisms such as CO₂ swelling and viscosity reduction a 3D compositional simulation model was built after a detailed fluid characterization study. Compositional simulation requires an equation of state model (EOS), which describes the relationship between pressure, volume and temperature of a gas or liquid. Thermodynamic properties and the equilibrium states are calculated by an equation of state by using ECLIPSE PVTi software (Schlumberger, 2005). Number of phases and composition of each phase was determined by solving EOS model.

EOS needs to be matched with laboratory experiments before it can be used to realistically predict the injected CO₂ behavior in the reservoir. Properties of pure components are defined accurately. However, oil and gas reservoirs may also contain heavy fractions whose properties are usually not accurate (Ahmed and Meehan, 2010). Heavy fractions composed of aromatic, paraffinic, and naphthenic compounds are not well defined. In our study, these are C₃₆₊ fractions. Table 16 presents the molar composition of the produced oil. Compositional simulators solve N_{c+2} equations for each grid (Schlumberger, 2005). Since, running a compositional simulation with 36+ components (N_c) will be computationally expensive, there is need to lump the components to reduce the CPU time. To do all these changes in an accurate way, we need to stick to laboratory observations.

Table 16 - Molar compositions of oil (Demir, 2016)

Component	Mol%	Component	Mol%	Component	Mol%
H ₂ S	0.00001	C ₁₀	13.359	C ₂₄	0.45

C ₉	12.69	C ₂₃	0.74		

To characterize the reservoir fluid, ECLIPSE PVTi was used (Schlumberger, 2005). Firstly, oil composition given in Table 16 is defined in PVTi. Default library was used to get physical properties of the components. Characterization of heavy plus components was carried out by using their corresponding molecular weights. There is minimum information about properties of heavy plus component so that it was used for tuning of equation of state. Properties of the components before regression and lumping are shown in Table 17. In the software, 3-Parameter Peng Robinson EOS which is a modified version of Soave Redlich Kwong EOS is used to calculate the phase behavior (Peng and Robinson, 1976).

Equation 5.5 presents the Peng Robinson EOS (Ahmed, 2000). In this equation, “V” is volume, “T” is temperature, “p” is pressure, and “R” is universal gas constant. Calculation of parameters “a” and “b” are given in Equation 5.6 and Equation 5.7 respectively. “T_c” and “P_c” are the critical temperature and critical pressure. In addition to these, equation of “α” is given in Equation 5.8. “m” given in Equation 5.9 was proposed by Peng and Robinson (1976) for heavier components and “ω” is the acentric factor (Ahmed, 2000). To match PVT experiments using the EOS an automatic nonlinear regression method embedded in Eclipse PVTi software was used. In order to match the saturation pressure acentric factor was adjusted. Volume parameters of components were then matched with the experimental data in such a way that “P_c*V_c=Z_{crit}*R*T_c” is satisfied for each component by adjusting Z factors ±10%. Viscosity of the components were matched similarly by Z_{crit} values. Detailed information about equation of state tuning is given in Section 5.6.

$$p = \frac{R \times T}{V - b} - \frac{a \times \alpha}{V \times (V + b) + b \times (V - b)} \quad (5.5)$$

$$a = 0.45724 \times \frac{R^2 \times T_c^2}{p_c} \quad (5.6)$$

$$b = 0.07780 \times \frac{R \times T_c}{p_c} \quad (5.7)$$

$$\alpha = (1 + m \times (1 - \sqrt{T}))^2 \quad (5.8)$$

$$m = 0.379642 + 1.48503 \times \omega - 0.1644 \times \omega^2 + 0.016667 \times \omega^3 \quad (5.9)$$

5.5 Lumping Scheme

As discussed above, number of components (39), needs to be reduced by lumping to decrease the simulation time. Lumping is grouping of the components into pseudo components. There are many possibilities for lumping process. For example, if we want to reduce the number of components to 7, there are 2,760,681 lumping possibilities. Therefore, a lumping scheme needs to be used.

To appropriately simulate CO₂ injection, there is need to define CO₂, N₂, H₂S and CH₄ as pure components. Therefore, they will not be lumped with other components. It is quite common to lump C₂-C₃ and C₄-C₆ based on their similar molecular weights (Khan et al., 1992). For C₇+, it is decided to use two pseudo components and Whitson's method was used to decide these groups (Whitson, 1983). According to Whitson (1983), C_n+ fractions can be lumped to multi carbon number groups (MCN) that can be found by Equation 5.10. Equation 5.11 was used to obtain the molecular weights separating each MCN group. Until now, apart from the already 6 components, C₇ to C₃₆ will be lumped into two groups so that N_g is 2. From Equation 5.11, molecular weight separating MCN group is found as 219. Therefore, C₇ to C₁₅ are grouped into one lumped parameter and C₁₆ to C₃₆ grouped to another. As a result, final components are CO₂, N₂, H₂S, C₁, C₂₋₃, C₄₋₆, C₇₋₁₆, C₁₆₋₃₆. Table 18 shows properties of components after lumping. Injected gas stream must be lumped with the same lumped components of the oil. Table 19 shows properties of injected gas stream components after lumping.

$$N_g = \text{Int}[1 + 3.3 \log_{10}(N - n)] \quad (5.10)$$

N_g= number of MCN groups (which is taken as 2 in our study)

N= number of carbon atoms of the last component which is 36 for our case

n= number of carbon atoms of the plus fraction which is 7 for our case

$$M_I = M_n(\exp((1/N_g)\ln(M_N/M_n)))^I \text{ which is equal to } M_I = M_n*(M_N/M_n)^{1/N_g} \quad (5.11)$$

M_N = molecular weight of the last component which is $M_{36}=500$ for our case

M_n = molecular weight of the + component which is $M_7=96$ for our case

Table 18 - Properties of components after lumping

5.6 Equation of State Tuning

EOS models are built based on empirical correlations, which may not perfectly match with specific cases so that there are some uncertainties from the beginning. Other uncertainties come to the play when heavy fractions are split, lumped and some of their properties are found by using mixing rules. Therefore, there is need to tune EOS by either trial and error procedure or by an automatic nonlinear regression (Ahmed, 2007). In this study, automatic nonlinear regression method was used to match EOS results with PVT lab data. Available PVT experiments for our case are, saturation pressure (P_b), constant composition expansion (CCE), and differential liberation expansion test (DLE), zero flash test and viscosity measurements, that are discussed in the previous chapter. For tuning, Coats and Smart Approach (1986), Whitson and Brule Approach (2000), Christensen Approach (1999), Ali and Al-Banbi Approach (2015), Aguilar and McCain Approach (2002), and Al-Meshari and McCain Approach (2005) can be used. Al-Meshari and McCain Approach (2005), which is the most accurate one was modified and used for tuning. Uncertainties in the properties of the plus fraction are the main problem while predicting volumetric behavior and thermodynamic properties by EOS. Small changes in the properties of plus fraction may have a big effect on PVT properties (Ahmed, 2007). Therefore, tuning was started by a property of a plus fraction. First, saturation pressure was matched by tuning the acentric factor of C_{18+} . Following that, volume shift parameters of all components were used for the regression of the volumetric data of CCE and DLE. Volume shift parameters were also tuned to match liquid density. Finally, viscosity was matched by tuning Z_{crit} , which is the ratio of molar volume of gas to the molar volume of ideal gas at critical temperature and pressure. Decreasing relative volume behavior (Figure 23) and decreasing formation volume factor with the pressure that is above the bubble point pressure is matched. As can be seen both the lumped model and the measured oil viscosity (Figure 27) and oil density (Figure 24) are decreasing until bubble point pressure and then increasing thereafter (Figure 27). There was a reasonable match for most parameters except for the gas oil ratio (Figure 25). It

was thought that might be a mechanical problem related to opening or closing the sampler, which may lead to releasing of gas.

5.7 Model Construction and History Matching

In this study, a previously developed geological model was used (Bender and Yilmaz, 2014). This geological model consists of 106704 grid blocks, 54 in the y direction, 152 in the x direction and 13 in the z direction corresponding to an area of 13.3 km² (Bender, 2013). Grid block size is 50 m in the x direction, 50 m in the y direction. In the z direction, grid block size is between 3 to 8 m. Model gross pore volume is 162 million m³. Model properties are given in Table 20. A three dimensional compositional reservoir simulation model was constructed by using Schlumberger's Eclipse 300 and Petrel software.

Table 20 - Summary of the reservoir model properties (Bender and Yilmaz, 2014)

<u>Parameters</u>	<u>Values</u>	<u>Units</u>
Number of cells in the x direction	152	
Number of cells in the y direction	54

Number of Gridblocks	106704	
x gridblock size	50	m
y gridblock size	50	m
z gridblock size	13	m
Total Pore Volume	162×10^6	m^3

History matching is a critical step to calibrate the model, which will be used to predict the reservoir performance. History match part covers 30 years of production and 10 years of injection periods. Production and injection periods are divided into 4 parts. These are primary production period, continuous gas injection period and water alternating gas injection periods and decline period after CO₂ flooding projects. Our strategy was tuning and matching during primary production period and then checking the others. History matching parameter selection is a crucial step to achieve correct predictions. In this study, matching parameters were decided based on the uncertainty. Uncertainty level of matching parameters is well discussed by Mattax and Dalton (1990). According to their study, aquifer connectivity, permeability anisotropy, high conductivity streaks, relative permeability functions, rock compressibility are some of the uncertain parameters and these parameters were used in our study. Firstly, reservoir pressure was matched by using reservoir volume as a control mode. Build up tests and static gradient data were used to match. No areal change was made during reservoir pressure matching period. To match the reservoir pressure, aquifer connectivity was decreased and total compressibility was tuned. Aquifer connectivity was

chosen to match the reservoir pressure because it has the highest uncertainty among other data. Therefore, history matching initiated by using aquifer connectivity. Fault transmissibility is another uncertain parameter due to limited data. To match the pressures of the regions close to the faults, fault transmissibility were tuned. As discussed in Section 5.3, drill stem test permeability is higher than the core permeability because there are vugs and fissures in this field and it is hard to see these in core analysis. Therefore, there is uncertainty in global permeability. To match the well pressures global horizontal permeability was increased. Cumulative oil, water, gas productions and breakthrough times were then matched by using oil rate as a control mode. To match the water and gas productions, vertical permeability to horizontal permeability ratio was decreased. Also, relative permeability data (endpoints) were tuned to match the water cuts and breakthrough times. Figure 28 shows the history match of the field oil-water-gas production rate, and pressure. Finally, individual well behaviors which are oil, water, gas productions, water cuts, gas oil ratios and log-derived saturations were matched by sticking to initial match. In this part global k_h , k_v/k_h ratio, fault transmissibility and endpoints were tuned. Only parameter that is changed regionally is Leveret J Function. As mentioned before, initial saturation distribution was conducted by using Leveret J Function. Match was performed by comparing the initial water saturations in well grids and log derived saturations from old and new wells. During the history match period for wells, knowledge of the completion data is very important to calibrate the model correctly. When engineer could not match the data, changing the properties around the well may not be realistic and correct. In this study, we experienced a situation, which can be a good example for that. Figure 29 presents the history match of oil and water productions for two wells. First, one matched perfectly but water rate could not be matched for the second one. When we checked the completion data, it was seen that there was a casing problem in this well and water was coming from the surface. As a result this well was not included in the matches.

Figure 28 - History match of the field oil water gas production rate and pressure

Figure 29 - History match for Well #14 and Well #12

Quality of history match was checked by well by well and was also checked by using Equation 5.12 which enables us to quickly check the whole field for all time steps for different parameters. This is also useful to show the quality of the match in one graph instead of many graphs. In this equation, “S” is the simulated value, “O” is the observed value, “ σ ” is the normalization parameter, “N” is the number of points and “M” is the match value, which shows the quality of the match (Schlumberger, 2013). The normalizing parameter is chosen such that “M” values calculated by this equation are graded from 1 (good) to 5 (poor) each value corresponding to 10% increments. Any raw match value below 10% is graded as 1. All raw values above 50% are graded 5. The interval in between is divided into three equally sized intervals, graded between 2 and 4. Values are assigned to different colors. Figure 30 shows history match analysis of oil production rate, oil production cumulative, water cut and pressure. In this figure, green dots represent a good match (i.e. $M \leq 1$), yellow dots represent a reasonable match (i.e. $1 < M \leq 4$), and red dots represents a bad match (i.e. $M > 4$). It can be observed that each well’s oil production rate, oil production cumulative, water cut and pressure had been matched less than 10% except for well #38 and well #3. A high permeability fault crosses Well #38 that results in decreased oil production and increased water cut in less than a month. This well was shut in after a month due to high water cut and then used for injection. Well #3 is located in an area with a high uncertainty. Excess water feeding this well could not be modeled resulting in a poor match.

$$M = \sqrt{\frac{1}{N} \sum_{i=1}^N \left(\frac{S_i - O_i}{\sigma} \right)^2} \quad (5.12)$$

Figure 30 - History match analysis of oil production cumulative, oil production rate, water cut & pressure

CHAPTER 6

OPTIMIZATION OF GAS INJECTION AND OIL RECOVERY

In this chapter, CO₂ injection methodologies are discussed and compared. Effect of changing injected CO₂ amount on CO₂ storage, oil recovery and economics were investigated by optimizing produced gas oil ratios and injection rates. Optimization of produced gas oil ratios and injection rates are essential to maximize the amount of CO₂ storage and oil recovery. Sensitivity of these parameters and their effects were discussed in this chapter.

6.1 Flue Gas Injection

Primary objective of this section is to maximize the amount of flue gas storage and secondary objective is to increase the oil recovery while maximizing the flue gas storage. To achieve these goals, history matched compositional simulation model was used for numerical predictions. Three different scenarios were built to understand the effect of the CO₂ solubility, effect of different gas oil ratio constraints, and effect of different injection rates on CO₂ storage and oil recovery. All simulation runs were started from 01.01.2016 and field production predictions for 100 years had been carried out under operational constraints. For all cases, maximum water cut for production wells was set as 100 % and minimum oil production for each production well was set as 0 stb/day to be able to continue the storage project in the absence of oil production. For injection wells, maximum bottom hole pressure was restrained as 131 bar that is 7 bars less than the initial reservoir pressure. Firstly, base case (do nothing case) was run for 100 years without any flue gas injection for comparison purposes. Field production was started with 31 production wells (Figure 15). Oil production continued for 29 years

until 2045. Figure 31 shows oil production cumulative, oil flow rate, average field pressure, water production rate vs date for the base case. Additional oil recovery and cumulative oil recovery were estimated as 89,965 sm^3 and 1,339,721 sm^3 corresponding to a recovery factor of 5.7 %.

Figure 31 - Field cumulative oil production, oil rate, pressure and water production rate for the base case

6.1.1 Effect of CO₂ Solubility

In this scenario, effect of CO₂ solubility in three phases on CO₂ storage and oil recovery was studied. Equilibration method was used to calculate CO₂ partitioning between oil and gas (Schlumberger, 2011). Oil and gas densities and fugacity were modeled by using 3-Parameter Peng Robinson EOS. Due to lack of CO₂ solubility data in water, CO₂ solubility was determined by using solubility data from the literature (Chang et al., 1996). First run was simulated without enabling the CO₂ solubility and second run was studied enabling the CO₂ solubility in three phases. For both of the runs, GOR constraint was set as 1000 sm³/sm³ and daily field gas injection was set as 50,000 sm³/day that is shown as “GOR-1000-Inj-50000” in Table 21. Flue gas injection was started in 01.01.2016 and continued for 100 years. Figure 32 shows cumulative oil production, gas in place, and CO₂ dissolved in aqueous phase for CO₂ solubility case. As can be seen from this figure cumulative oil production and gas in place are very close to each other and gas in aqueous phase is very low for CO₂ solubility case. For CO₂ solubility case, cumulative flue gas storage is 1,105 MMsm³, total CO₂ storage is 268.29 MMsm³, 47 MMsm³ of CO₂ is dissolved in oil, 19.86 MMsm³ of CO₂ is dissolved in water and recovery factor is 10.09%. For without CO₂ solubility case, cumulative flue gas storage is 1,087 MMsm³, total CO₂ storage is 262.52 MMsm³ and recovery factor is 10.06%. As can be seen from Figure 32, both results are very close to each other. Reservoir pressure is always below the minimum miscibility pressure resulting in immiscible gas injection in all cases. For immiscible gas injections, effect of CO₂ solubility is very low when compared to miscible gas injections. Yet another reason is that there is no active aquifer or water injection for both cases where effect of CO₂ solubility in water is important. For the scenarios discussed in other sections CO₂ solubility option was enabled for more accurate results. Table 21 shows summary of the results for both of the cases.

6.1.2 Effect of GOR

For storage objective, one of the most important factors affecting amount of gas sequestered is produced GOR constraint. Different GOR constraints (1, 500, 1000, and 2000 sm^3/sm^3) were used in production wells to see the effects of GOR constraint on storage and recovery. When the simulated GOR reached the set GOR value in each well, perforations responsible for this increase was shut down. For all cases, daily field gas injection rate was set as 50,000 sm^3/day and CO_2 solubility option was enabled in all scenarios. Figure 33 shows gas in place, CO_2 dissolved in aqueous phase, cumulative oil production, and average reservoir pressure for each scenario. For GOR-1 case, there was almost no oil production because gas breakthrough occurred quickly in already CO_2 flooded oil field. As the wells were closed due to GOR-1 constraint, reservoir pressure increased quickly. As a result, amount of gas storage did not increase after 24 years (Figure 33). After this case, GOR constraint was increased. When GOR-1000 case was run it gave the maximum gas storage and oil recovery among the values discussed here. Totally, 1.1 billion sm^3 of flue gas stored and oil recovery factor increased from 5.7% to 10.09% for GOR-1000 case. Following that, GOR-2000 was tried but did not give good results in terms of gas storage and oil production. As can be seen from Figure 33, reservoir pressure reached to the maximum value in 44 years that lead to decrease in storage and recovery. Pressure had started to decrease after 10 years of injection for GOR-1000 and GOR-2000 cases due to increased GOR ratio that lead to better sweep efficiency (Figure 33). Gas production control plays a crucial role not only for gas storage but also for oil recovery. There are two reasons for that. First, GOR management contributes to better sweep efficiency. Second, oil production decreases after gas breakthrough due to high mobility of gas. Results show that there is an optimum value for GOR which maximize the amount of gas storage. Also, maximum oil recovery was achieved by the optimum GOR which maximized gas storage. Detailed results for each case are given in Table 21. Table 21 presents results for all scenarios, the number written after “GOR” represents GOR value and the number written after “Inj” represents daily injection rate.

Figure 33 - Gas in place and CO₂ dissolved in aqueous phase, cumulative oil production and average reservoir pressure for the GOR Case

6.1.3 Effect of Injection Rates

Optimization of injection rates is absolutely necessary to maximize the storage capacity of the reservoir and to increase the oil recovery. Five different injection rates (40,000, 50,000, 75,000, 100,000, and 150,000 sm^3/day) were used to study sensitivity of injection rates to production and storage. For all cases, GOR constraint was set as 1000 sm^3/sm^3 and CO_2 solubility option was enabled. Simulation time, 100 years, was adjusted to determine the maximum storage capacity of the reservoir before exceeding the regulated pressure for all cases. Injection rate for each well was constrained by the bottom hole pressure of 131 bars which is 95% of the initial reservoir pressure. Maximum flue gas storage of 1.10 billion sm^3 and additional oil recovery of 1.12 MMbbl was achieved by 50,000 sm^3 of daily flue gas injection and maximum additional oil recovery of 1.17 MMbbl was reached by 40,000 sm^3 of daily flue gas injection (Table 21). CO_2 storage capacity and oil recovery decreased with higher injection rates. As can be seen from Figure 34, higher injection rates caused quick pressure buildup in the reservoir so that CO_2 storage capacity was limited by decreased injectivity. Increase in pressure was quick and continuous for higher injection rates; 75,000, 100,000, and 150,000 sm^3/day . However, pressure increased, decreased and then increased for lower injection rates; 40,000, 50,000 sm^3/day because reservoir oil production continued with high daily rates that leads to decrease in reservoir pressure. Also, high oil recoveries were achieved at early times with high gas injection rates but after that oil recoveries decreased due to increase in reservoir pressure. In addition to these, high gas injection rates resulted in early gas breakthrough that increased the gas oil ratios and reduced the oil recovery in long term. Figure 35 shows the amount of flue gas storage vs recovery factor for all cases.

Figure 34 - Gas in place and CO₂ Dissolved in aqueous phase, cumulative oil production and average reservoir pressure for the injection rate case

Figure 35 - Amount of flue gas storage vs recovery factor

6.2 Pure CO₂ Injection

In this section, pure CO₂ injection for storage and EOR purposes is discussed. History matched compositional simulation model was used for numerical predictions. All simulation runs were started from 01.01.2016. Field production predictions for 100 years had been performed under operational constraints. Maximum water cut for production wells was set as 100% and minimum oil production for each production well was set as 0 stb/day to be able to continue the storage project in the absence of oil production. For injection wells, maximum P_{bh} was restrained as 131 bar that was 7 bar less than the initial reservoir pressure.

6.2.1 CO₂ Storage

Equilibration method was used to calculate CO₂ partitioning between oil and gas (Schlumberger, 2011). Oil and gas densities and fugacity were modeled by using 3-Parameter Peng Robinson EOS. Due to lack of CO₂ solubility data in water, CO₂ solubility was determined by using solubility data from literature (Chang et al., 1996). GOR was set as 1000 sm³/sm³ and daily field gas injection was set as 50,000 sm³/day. CO₂ injection was started in 01.01.2016 and continued for 100 years. Gas storage and oil recovery continued to increase after 100 years. Totally, 1.63 billion sm³ of CO₂ was stored, 342 MMsm³ of CO₂ was dissolved in oil and 80 MMsm³ of CO₂ was dissolved in water. Additional oil production was 1.57 MMsm³. Figure 36 shows cumulative oil production, gas in place, and CO₂ dissolved in aqueous phase for CO₂ injection case. As can be seen from Figure 36, reservoir pressure did not reach to its maximum value. As a result, oil recovery and CO₂ storage increased continuously. Therefore, it can be said that CO₂ storage project can continue more than 100 years, if the injected gas is CO₂. After 2024, reservoir pressure started to decrease because produced volume was larger than injected volume. Around 2040, reservoir pressure started to increase again due to decrease in oil production rates that can be seen from the decrease in the slope of the oil production cumulative part of the Figure 36. 1040 sm³ of CO₂ was injected to produce 1 sm³ of oil. CO₂ injection enhances the oil recovery by viscosity reduction and swelling effects. Storage project had a positive effect on oil recovery that increased the oil recovery factor from 5.7 % to 12% and also increased the field's life. It was determined that the discussed field is a good candidate for CO₂ storage. Totally 1.63 billion sm³ of CO₂ could be sequestered in this field. Figure 35 presents change of CO₂ gas storage with recovery factor. As can be seen from this figure, CO₂ injection case steps out of the line due to its favorable properties when compared with flue gas injection. During the storage project, most of the CO₂ was trapped by structural and stratigraphic trapping mechanism. Only 25.98% of the sequestered CO₂ was trapped by solubility trapping mechanism.

Figure 36 - Cumulative oil production, gas in place, CO₂ dissolved in aqueous phase and pressure for the CO₂ storage case

6.2.2 CO₂ EOR

To optimize the CO₂ flooding project, different operating parameters were studied; producing well gas oil ratio (GOR) constraint and injection rates. Firstly, injection rates were optimized to maximize the oil recovery. For all cases, producing GOR constraint was set as 1000 sm³/sm³. Injection rate for each well was regulated by the bottom hole pressure constraint of 131 bars, which was 95% of the initial reservoir pressure. Studied injection rates were 50,000, 100,000 and 200,000 sm³/day. Maximum oil recovery was achieved by 50,000 sm³/day of CO₂ injection. It was found that higher injection rates resulted in lower oil recoveries due to quick breakthrough, quick pressure build up and lower sweep efficiency. Producing GOR is one of the most important factors affecting oil recovery. Three different GOR constraints were set for production wells; 1, 1000, and 4000 sm³/sm³. Daily gas injection rate was set as 50,000 sm³/day for all cases. Higher GOR constraint decreased the oil recovery due to high mobility of gas. Maximum oil recovery was achieved by 50,000 sm³/day of CO₂ injection and 1000 sm³/sm³ GOR (Figure 37). Additional oil production was 1.56 MMsm³ and recovery factor increased from 5.7 % to 12 %. 1040 sm³ of CO₂ was injected to produce 1 sm³ of oil. Totally, 1.63 billion sm³ of CO₂ was stored.

Figure 37 - Cumulative oil production, gas in place, CO₂ dissolved in aqueous phase and pressure for the CO₂ EOR case

6.3 Natural Gas Injection for EOR

As discussed in Chapter 4, there are three gas reservoirs around the mature oil field and all of them consists mostly methane and CO₂. In this section, injections of gases produced from these fields were simulated by using the aforementioned 3D compositional model. Main aim of this part is to find the effect of these gases on oil recovery and probable lifetime of these gas reservoirs.

All simulation runs were started from 01.01.2016 and field production predictions had been carried out until depleting the gas source. For all cases, maximum water cut for production wells was set as 95 % and minimum oil production for each production well was set as 1 stb/day. For injection wells, maximum bottom hole pressure was restrained as 131 bar that is 7 bar less than the initial reservoir pressure. Field production was started with 31 production wells. Daily gas injection rate was set as 50,000 sm³/day for all cases and producing GOR constraint was set as 1000 sm³/sm³. It has been found that gas from Source A can feed the oil reservoir for 45 years, whereas gas source B can survive for 5 years and gas source C can last for 2 years. It was decided that it is not necessary to invest on the transportation of gas from gas source B and gas source C due to limited amount of OGIP and limited project time. Figure 38 shows cumulative oil productions for each case. It has been found that highest recovery was obtained by injecting gas source A's gas which has the highest CO₂ percentage. Additional oil recovery and cumulative oil recovery was estimated as 691,508 sm³ and 1,941,264 respectively with a recovery factor of 8.8 % for gas source A case.

Figure 38 - Cumulative oil production vs time

6.4 A Discussion on Gas Saturation Distributions

In this section, CO₂ saturation distributions from 2002 to 2116 are discussed for continuous CO₂ flooding case. At the end of this section continuous CO₂ flooding case, flue gas injection case, and Source A gas injection cases are compared by evaluating gas saturation distributions at the end of each project.

Figure 39 presents the CO₂ saturation distributions for the CO₂ injection project applied between 2003 and 2012. As discussed before, continuous CO₂ injection project was started in 2003 by using 7 injection wells and had been continued until 2007. As can be seen from Figure 39, CO₂ saturation increased around the injection wells after 4 years of continuous CO₂ injection. Due to high gas oil ratios in the production wells and low sweep efficiencies, continuous CO₂ injection was converted to water alternating gas injection in 2007. After the start of the water alternating gas injection project in 2007, CO₂ saturation started to decrease due to decreased CO₂ injection from injection wells as well as due to increase in CO₂ productions from production wells. In addition to these, CO₂ injection decreased during WAG project because of injectivity problems. CO₂ injectivity of injection wells decreased while moving from water to CO₂ injection. Water blocked high permeable paths of CO₂ around the injection wells. On the other hand, CO₂ production from production wells increased due to the mobility contrast between oil and CO₂. Most of the produced CO₂ was from the continuous CO₂ injection project. In 2012, CO₂ injection project was stopped. After 2012, CO₂ saturation in the field decreased quickly due to high mobility contrast between CO₂ and oil. Last part of Figure 39 presents the CO₂ saturation distribution after 4 years of stopping the project.

Figure 39 - 3D view of CO₂ saturation distribution from 2003 to 2016 (Real case)

Figure 40 and Figure 41 show the CO₂ saturation distributions for the CO₂ injection case (GOR: 1000 sm³/sm³, Injection Rate: 50,000 sm³/d) from 2021 to 2116. After 5 years of continuous injection CO₂ started to move. Saturation of CO₂ increased quickly in the zone that is showed by a circle in the first part of Figure 40. This part of the reservoir is surrounded by permeable faults which have higher permeability than other parts. Increase in CO₂ saturation had continued to increase in this zone until 01.01.2081 (65 years). After 65 years, CO₂ saturation started to decrease in this area due to high permeability connection between production and injection wellss (Figure 41). There was both lateral and vertical migration of CO₂ but only one of them was dominant. Figure 42 presents the cross sectional view of CO₂ saturation distribution at the end of the CO₂ injection project (01.01.2116). As can be seen from this figure, there was an upward migration of CO₂ such that CO₂ plume moved to upper layers and accumulated at the top layer due to buoyancy of CO₂. In this reservoir, buoyancy force is large because of immiscible conditions and high density difference between the heavy oil and CO₂. Outcome of the upward migration was decrease in oil recovery. Only a small portion of oil could be displaced and produced from the bottom layers. It can be said that structural trapping is a very important trapping mechanism in this reservoir because of the buoyance forces. There has to be a good seal at the top of the reservoir to protect the CO₂ migration to the surface. Figure 43 shows gas saturation distribution of pure CO₂ flooding case, flue gas injection case, and Source A gas injection case at the end of each project. Injected gas moved to shallower sections of the reservoir in all cases. Source A gas moved to a smaller area when compared to that of flue gas injection and CO₂ injection due to limited amount of gas injection and shorter project time. Gas saturation distributions were higher for CO₂ flooding case when compared to flue gas injection case where less gas was injected. CO₂ has some favorable properties; oil swelling, viscosity reduction and increased injectivity. With the increase in pressure, more CO₂ dissolves in oil and oil recovery increases. Injectivity increases with increase in oil production and dissolution of CO₂. Therefore, CO₂ was injected more, occupied a larger area, and contacted with more oil.

6.5 Economic Investigation of Flue Gas Injection, CO₂ Injection and Natural Gas Injection

Economic model used in this study is built based on the requirements of the project. During the development of the storage or EOR project, there is a need for economic evaluation before making the final decision. For CO₂ storage and EOR projects, there are many factors that may affect the project economics. Complexity of these projects can be simplified by using objective functions. In this study, amount of CO₂ storage and net present value (NPV) are the objective functions. Our aim is to maximize the amount of CO₂ storage, and maximize the NPV of the project. Built economic model was used to calculate the NPV of the project for different scenarios. An Excel code was written to perform the economic analysis. During the construction of the model, Bender's (2011) and Ghomian's (2008) economic models were modified based on the project requirements and used. Data from the simulator is used as input in the economic model; these are; time, oil production, water production, CO₂ production and injection rates (Table 22). Table 23 shows the economic inputs used for the base case (Bender, 2011). Capital investment cost was not used for the base case and CO₂ price was used for only pure CO₂ injection case. Table 24 presents economic model outputs which were calculated by using input data from the simulator, economic inputs, and excel sheet.

Table 22 - Economic model input data from the simulator

	Units	Symbol
Time	day	t
Oil Production Rate	sm ³ /d	Opro
Water Production Rate	sm ³ /d	Wpro
CO ₂ Injection Rate	sm ³ /d	Ginj
CO ₂ Production Rate	sm ³ /d	Gpro
Water Injection Rate	sm ³ /d	Winj

Table 23 - Economic inputs

Capital Investment (Compressor+Workover)	MM\$	30
Oil Price	\$/sm ³	314.491
Oil Price Inflation (Increase)	fraction/yr	0.100
Royalty	fraction	0.125
CO ₂ Price	\$/ton	10
Op Cost Inflation	frac/yr	0.014
Recycle and Injection Cost for CO ₂	\$/sm ³	0.011
Lift Cost	\$/sm ³	1.250
Discount rate	frac/yr	0.120
Government Tax Rate	frac	0.200
CO ₂ Credit +	\$/ton	0.000
Recycle and Injection Cost for Water	\$/sm ³	0.620

Table 24 - Economic model outputs

Year	yr
Oil Revenue	MM\$/yr
CO ₂ Purchase Cost	MM\$/yr
Gas + Water Recycle & Operation Cost	MM\$/yr
Lift Cost	MM\$/yr
Income Before Tax	MM\$/yr

Income After Tax	MM\$/yr
Cumulative NCF after Tax	MM\$
Discounted NCF After Tax	MM\$
Cum Discounted NCF After Tax	MM\$

Calculation algorithm to determine the net present value of the project is given below;

- Oil Revenue (MM\$/yr)=

$$\frac{\text{Oil Production}(sm^3/\text{day}) * 365.25 (\text{day} / \text{yr}) * \text{Oil Price}(\$/sm^3)}{10^6} \\ * (1 - \text{Royalty}) * ((\text{Oil Price Inflation} + 1)^t)$$

- CO₂ Purchase Cost (MM\$/yr)=

$$\frac{\text{Max}((CO_2 \text{ Inj}(sm^3/\text{day}) - CO_2 \text{ Pro}(sm^3/\text{day})), 0) * 365.25 * CO_2 \text{ Price}(\$/sm^3)}{10^6}$$

- Gas and Water Recycling, Injection, and Operational Cost (MM\$/yr)=

$$\left(\frac{(CO_2 \text{ Pro}(sm^3/\text{day}) * \text{Recycle Cost}^{CO_2}(\$/sm^3) + (CO_2 \text{ Inj}(sm^3/\text{day}))}{10^6} \right. \\ \left. \frac{(-CO_2 \text{ Pro}(sm^3/\text{day})) * CO_2 \text{ Inj Cost}(\$/sm^3)}{10^6} \right. \\ \left. + \frac{\text{Water Pro}(sm^3/\text{day}) * \text{Recycle Cost}^{Water}(\$/sm^3)}{10^6} \right) \\ * ((\text{Operational Cost Inflation} + 1)^t)$$

- Lift Cost (MM\$/yr)=

$$\frac{(\text{Oil Pro}(sm^3/\text{day}) + \text{Water Pro}(sm^3/\text{day})) * 365.25}{10^6} \\ * \text{Lift Cost}(\$/sm^3) * ((\text{Operational Cost Inflation} + 1)^t)$$

- Income Before Tax (Taxable Income), (MM\$/yr)=

$$\text{Oil Revenue}(\text{MM } \$/\text{yr}) - \text{CO}_2 \text{ Purchase Cost}(\text{MM } \$/\text{yr}) - (\text{Gas} + \text{Water Recycle} + \text{Operation Cost})(\text{MM } \$/\text{yr}) - \text{Lift Cost}(\text{MM } \$/\text{yr})$$
- Cumulative Net Cash Flow (NCF) Before Tax, (MM\$)=
 -First Calculation;

$$= \text{Income Before Tax}(\text{MM } \$/\text{yr}) * t(\text{yr}) - \text{Total Investments}(\text{MM } \$)$$
 -Other Calculations (at time = t_i);

$$= \text{Income Before Tax}(\text{MM } \$/\text{yr}) * (t_i(\text{yr}) - t_{i-1}(\text{yr})) + \text{NCF Before Tax}_{i-1}$$
- Depreciation (MM\$/yr)=

$$\text{Capital Investment}(\text{mm } \$) * \text{Max}((0.3094 - (t(\text{yr}) - 0.5) * 0.0476), 0)$$
- CO₂ Credit + (MM\$/yr)=

$$(\text{CO}_2 \text{Inj}(\text{sm}^3/\text{day}) - \text{CO}_2 \text{Pro}(\text{sm}^3/\text{day})) * 365.25 * \text{CO}_2 \text{ Credit}(\text{\$/sm}^3) * 10^{-6}$$
- Government Income Tax (MM\$/yr)=

$$(\text{Income Before Tax}(\text{MM } \$/\text{yr}) - \text{Depreciation}(\text{MM } \$/\text{yr}) + \text{CO}_2 \text{ Credit}(\text{MM } \$/\text{yr})) * \text{Government Tax Rate}$$
- Income After Tax (MM\$/yr)=

$$\text{Income Before Tax}(\text{MM } \$/\text{yr}) - \text{Government Income Tax}(\text{MM } \$) + \text{CO}_2 \text{ Credit}(\text{MM } \$/\text{yr})$$
- Cumulative NCF After Tax (MM\$)=
 -First Calculation;

$$= \text{Income After Tax}(\text{MM } \$/\text{yr}) * t(\text{yr}) - \text{Total Investments}(\text{MM } \$)$$
 -Other Calculations (at time = t_i);

$$= \text{Income After Tax}(\text{MM } \$/\text{yr}) * (t_i(\text{yr}) - t_{i-1}(\text{yr})) + \text{Cumulative NCF Before Tax}_{i-1}$$
- Discounted NCF After Tax (MM\$)=

-First Calculation;

$$= \frac{\text{Cumulative NCF After Tax (MM\$)}}{(1+\text{Discount Rate})^{t=0}}$$

-Other Calculations (at time= t_i);

$$\frac{\text{Cumulative NCF After Tax (MM\$)}_{t=i} - \text{Cumulative NCF After Tax (MM\$)}_{t=i-1}}{(1+\text{Discount Rate})^{t_i}}$$

- Cumulative Discounted NCF After Tax (MM\$)=

-First Calculation = Discounted NCF After Tax (MM\$)_{t=0}

-Other Calculations (at time= t_i);

$$= \text{Discounted NCF After Tax (MM\$)}_{t=i} + \text{Discounted NCF After Tax (MM\$)}_{t=i-1}$$

Simulation results obtained from the simulator were imported to the code written and NPV for each case was calculated. Table 25 shows the results for each case. It has been found that highest profit can be achieved by pure CO₂ injection GOR-1000-Inj-50000 case. In addition, highest amount of CO₂ was stored with that case.

Table 25 - Economic analysis results

NPV, MM\$	Case Name	Injected Gas
18.29	Base Case	-
-25.31	GOR-1-Inj-50000	Flue Gas
111.71	GOR-500-Inj-50000	Flue Gas

CHAPTER 7

CONCLUSIONS

Different gas injection scenarios in a mature oil field were studied using a history matched compositional numerical model. Due to the availability of nearby flue gas source (cement factory) and a pipeline for gas transportation, which was built to transport natural gas from the oil field to cement factory, there is a huge opportunity to decrease project costs. The results of the full-field compositional simulation have been used for an examination of the raw flue gas injection, CO₂ injection, natural gas injection, operating parameters and CO₂ solubility. Maximum CO₂ storage and oil recovery can be achieved by pure CO₂ flooding due to solubility trapping mechanism, which becomes dominant with increased CO₂ concentration and pressure. CO₂ flooding and flue gas flooding give same oil recovery for a certain time or until a certain reservoir pressure. After that, effects of CO₂ on oil increase its effectiveness. These effects are oil swelling, viscosity reduction and interfacial tension reduction due to increased CO₂ solubility. In addition, effect of CO₂ solubility becomes very important after a threshold time. CO₂ dissolved in aqueous phase increases continuously corresponding to high amount of CO₂ storage. Influence of CO₂ solubility during immiscible flue gas injection is low but it is very important during pure CO₂ injection. For mature oil reservoirs, pressurizing the reservoir with the flue gas and then injecting CO₂ might give better oil recoveries. In this way, N₂ in flue gas will provide energy to push the oil and CO₂ will dissolve in oil. In addition to these, it has been observed that water production decreases during pressurization by gas injection. Pressure of the oil production layer increases and becomes more than the underlying layer's, which is the source of the water. Highest oil recovery and gas storage can be achieved with optimized operating constraints targeting the sweep efficiency. With an increase in sweep efficiency,

reservoir gas storage capacity and oil recovery will increase. Lower GOR values as limiting criteria on production wells lead to quick pressure increase that decreases the project life, oil recovery and amount of CO₂ storage. On the other hand, higher GOR values give rise to gas production that in turn decrease oil recovery and gas storage with increased gas mobility and decreased sweep efficiency. High gas injection rates cause reduced injectivity due to quick pressure buildup that leads to early gas breakthrough. Both of these may cause reduction of both oil recovery and storage.

A comparative study was conducted to examine the efficiency of flue gas injection compared to CO₂ injection for simultaneous EOR and storage purposes. Results showed that;

1. Pure CO₂ injection leads to higher oil recovery and CO₂ storage, if injection continued for at least 25 years. Before this threshold injection time, flue gas injection and pure CO₂ injection resulted in comparable oil recoveries.
2. Amount of flue gas storage was determined as 1.1 billion sm³ and 268 MMsm³ of this gas was CO₂. 47 MMsm³ of CO₂ was dissolved in oil and 19 MM sm³ of CO₂ was dissolved in aqueous phase. Additional cumulative oil production was calculated as 1.12 MMsm³ with a recovery factor of 10.09%. 1000 sm³ of flue gas was injected to produce 1 sm³ of oil. NPV of the project was found as \$141.63 MM.
3. Totally 1.63 billion sm³ of CO₂ was sequestered and 1.57 MMsm³ of oil was produced with continuous pure CO₂ flooding. 342 MMsm³ of CO₂ was dissolved in oil and 80 MM sm³ of CO₂ was dissolved in aqueous phase. 1040 sm³ of CO₂ was injected to produce 1 sm³ of oil. NPV of the project was found as \$197.71 MM.
4. It was observed that most of the CO₂ was trapped by structural and stratigraphic trapping mechanism. 26% of the sequestered CO₂ was trapped by solubility trapping mechanism for pure CO₂ injection case.

5. Pressurizing the reservoir with flue gas injection followed by pure CO₂ injection may improve the project economics. However, pure CO₂ injection is the right strategy to maximize the CO₂ storage.
6. Limiting the production wells with lower GOR constraint, caused the wells shut in due to quick breakthrough and reservoir pressure increased quickly which lead to diminished storage and oil recovery. Also, higher GOR values were resulted in low storage and recovery due to high gas mobility when compared with oil. Management of GOR values contributed to better sweep efficiency and better pressure management.
7. Injection rates need to be optimized to maximize the flue gas storage. Quick pressure buildup occurred with higher injection rates so that gas storage was reduced due to decreased injectivity. With higher injection rates, higher oil recoveries achieved at early times of the project.
8. In this reservoir, buoyancy force is large because of the immiscible conditions and high density difference between oil and CO₂. Outcome of the upward migration was decrease in oil recovery. Only a small portion of oil could be displaced and produced from the bottom layers. It can be said that structural trapping is a very important trapping mechanism in this reservoir because of buoyancy.
9. It was decided that not to invest on the transportation of gas from gas source B and gas source C due to limited gas in place and shorter project time. Gas source B can only support the reservoir for 5 years and gas source C can support the reservoir for 2 years.

CHAPTER 8

RECOMMENDATIONS AND FUTURE WORK

Even though a comprehensive study on CO₂ sequestration and EOR was conducted, there are some factors that were not considered. For example, mineral trapping, which takes long times from hundreds to thousands of years, was neglected. Modeling the mineral trapping during CO₂ storage requires additional laboratory tests and might be time consuming while working on full field simulations. Since our aim was to maximize both storage and recovery, a water injection scenario was not included. Water alternating gas injection methodology might be studied to increase recovery. Required number of additional wells, well locations, and well configurations might be optimized by maximizing storage and NPV. To add these factors, experimental design and response surface method can be used that will decrease the number of simulations.

CURRICULUM VITAE

PERSONAL INFORMATION

Surname, Name: Bender, Serdar
Nationality: Turkish (TC)
Phone: +90 555 624 97 96
Email: serdar.bender@gmail.com

EDUCATION

University of Texas at Austin, Austin, Texas, USA
M.Sc. in Petroleum Engineering (2011)

Middle East Technical University, Ankara, Turkey
B.Sc. in Petroleum Engineering (2008)

PROFESSIONAL EXPERIENCE

Year	Place	Enrollment
2011-Present	TPAO	Reservoir Engineer
2009-2011	UT Austin	Research Assistant
2008-2009	TPIC	Production Engineer
